Drought in Sierra Streams

Long ago naturalist John Muir extended an open invitation to harken to the rugged beauty and wonder of the high mountains. Listen to the sounds of gushing streams as they roll through wild canyons, amid gardens of rocky meadows. Wander, surrounded by the forest and snowy peaks of the Sierra Nevada.

Today, however, these places are in peril. That's according to a new study out of UC Santa Barbara's [Sierra Nevada Aquatic Research Lab](#) in Mammoth Lakes, part of the university's Natural Reserve System. The paper shows the risk of drought, in particular, may threaten the aquatic life that is integral to headwaters and the rivers into which they drain. The results appear in the journal [Freshwater Biology](#).

"The high elevation zone you love to hike around in, and streams that you love to go fishing in, and places that you look to as your refuge for solace are changing," said lead author [David Herbst](#), a research scientist at UC Santa Barbara's Marine Science Institute. "And climate forecasts suggest they could be disappearing."

To understand how these montane streams respond to drought, Herbst and collaborators tracked the range and diversity of aquatic invertebrates from 2002 through 2015.

Scientists divide streams into roughly two types of habitats: riffles and pools. Riffles are shallow, rocky areas with relatively strong currents. Pools are the deeper areas that alternate with riffles. Different species live in these different habitats, with the most sensitive creatures preferring the swifter waters of the riffles, Herbst

explained.

But as streams dry up, riffles disappear and pools can become disconnected. This reduces the richness of the stream community and results in a simpler food web. For instance, large algae-eating and filter-feeding invertebrates, which are prime food for larger animals, like birds and fish, tend to disappear.

The mayfly *Ironodes* has been decimated as the riffle habitat in which it usually lives dried up.

Mountain streams can bounce back, according to the scientists. In fact, it wasn't until several years into the drought that the team observed a precipitous decline in biodiversity and the reorganization of the food web. But increased volatility in the

climate could prevent recovery even when water returns.

When flows do return, they increasingly come back in excess, in what climatologists call a whiplash. “We’re swinging from one extreme of drought to another extreme of flooding,” said Herbst, “and how this affects stream communities is not well understood.” These wide variations in flow may actually do more harm to the ecosystems than good.

Normally perennial mountain streams may become intermittent, with disconnected stretches persisting for long periods. This is standard in coastal creeks, and the wildlife there has adapted to these conditions. There’s a whole community of insects, and even some amphibians and fish, in coastal watersheds that can survive these intermittent flow regimes. But this is not common in the high Sierra Nevada.

And California is starting to see more precipitation fall as rain than snow, which can be just as devastating to mountain streams as the overall drought. Flow from rainwater is swifter and more variable than the steady flow provided by snowmelt. Rain comes on quickly and rushes through. Snow lingers, providing a longer, slower discharge that peaks in the late spring, rather than in winter. Snow also recharges groundwater far better than rain. Ultimately these differences set the conditions for what types of communities live in the streams, Herbst explained.

What’s more, mountain streams play an outsized role in their watersheds. A small pond or creek at the headwaters of a river can be more critical to the resiliency of the ecosystem than miles of downstream habitat. It’s far easier for biodiversity to flow back downstream after a disturbance than to creep its way up the watershed. And if these mountain refuges run dry, there’s nothing farther upstream to reinhabit them.

“This scenario points out what you want to search for in making conservation decisions about what to protect in the mountains,” said Herbst. “In what areas might there be these potential reservoirs from which recolonization could occur?”

California saw tremendous rains this past winter, and Herbst is waiting to see what the runoff will be like this spring. He’s currently investigating how the ecosystems respond to wet years like 2019. But conditions are bound to change again, and he’s concerned about the whiplash trend.

“The drought’s over for now, but we could have said that back in 2011, too, when we had another wet year like this. And that was followed right on the heels by four

years of the most historic drought in California,” Herbst said. “One year does not mean relief from the long-term effects of climate change.”

About UC Santa Barbara

The University of California, Santa Barbara is a leading research institution that also provides a comprehensive liberal arts learning experience. Our academic community of faculty, students, and staff is characterized by a culture of interdisciplinary collaboration that is responsive to the needs of our multicultural and global society. All of this takes place within a living and learning environment like no other, as we draw inspiration from the beauty and resources of our extraordinary location at the edge of the Pacific Ocean.
